Exercise: Introduction to Seaborn

Summary

This exercise uses a range of visualizations to explore data from the California Solar Initiative (CSI) program. The program ran from 2007 to 2019 and provided incentive payments for installing solar panels on California buildings. Homeowners and firms carrying out solar projects would apply to the program for the payments, and the exercise examines data from those applications.

Input Data

The input data is <code>ca_csi_2020_pkl.zip</code>, a zipped pickle file that will need to be downloaded from the course Google Drive folder. It contains one record for every CSI application, and it was last updated in early 2020. The full database contains 124 variables but for this exercise it has been trimmed down to thirteen: <code>"incentive"</code>, the dollar value of the incentive payments provided on the project; <code>"total_cost"</code>, the total cost of the project; <code>"nameplate"</code>, the project's rated DC power output in kW; <code>"app_status"</code>, the status of the application; <code>"sector"</code>, the host sector where the project was built (residential, commercial, etc.); <code>"county"</code>; <code>"state"</code>; <code>"zip"</code>; <code>"completed"</code>, the date the final incentive payment was sent; <code>"third_party"</code>, a string indicating whether the owner of the solar array is not the host customer; <code>"inst_status"</code>, the status of the system; <code>"type"</code>, a variable indicating whether the array tracks the sun or is fixed; and <code>"year"</code>, the year from the <code>"completed"</code> field. <code>firstlines.csv</code> provides a few lines from the file.

Deliverables

The deliverable for this assignment is a script, **figures.py**, that generates a range of figures using pandas and seaborn.

Instructions

- 1. Import pandas and matplotlib.pyplot, and import seaborn as sns.
- 2. Set the default DPI for plots to 300. Seaborn is built on Matplotlib so this will set the resolution of Seaborn plots as well.
- 3. Set the default style for Seaborn by calling sns.set_theme() with the argument style="white".
- 4. Create dataframe pv by using pd.read_pickle() to read "ca_csi_2020_pkl.zip".
- 5. Print an informative message and then call the .info() method on pv . The .info() method prints the name of each column, the column's count of non-null values, and the column's datatype.
- 6. Set up a list called catvars that includes the strings 'app_status', 'sector', 'state', 'inst_status', and 'type'. All of these are categorical variables.
- 7. Produce a quick overview of the values taken on by the categorical variables. Use variable var to loop over catvars and within the loop do the following:
 - 1. Print var .
 - 2. Print the result of calling .value_counts() on the var column of pv.
 - 3. Set fig equal to the result of calling sns.catplot() with arguments y=var, data=pv, and kind="count". For future reference, note that catplot() produces Figure-level plots (see the notes section for more discussion).

- 4. That's it for the loop. It is not necessary to save this batch of plots: they're just temporary figures showing one approach for getting a sense of what's in an unfamiliar database.
- 8. Now filter the dataset down to residential projects that have been completed and are installed. Here we'll do it in three steps because that would be convenient if the process seemed to eliminate too many records and we needed to go back to see which comparison was filtering them out. First, set res equal to the result of calling .query() on pv with the argument "sector == 'Residential'".
- 9. Next, set res equal to the result of calling .query() on res with the argument "app_status == 'Completed'"
- 10. Finally, set res equal to the result of calling .query() on res again but this time with the argument "inst_status == 'Installed'".
- 11. Print a message indicating the number of original records in pv and the number in res after filtering.
- 12. Convert the "year" column of res to an integer by using the .astype(int) method. (FAQ1)
- 13. Now we'll build a couple of additional figures showing project counts, and this time we'll save them. Start by using variable var to loop over a list consisting of the strings "third_party" and "year". Within the loop do the following:
 - 1. Set fig equal to the result of calling sns.catplot() on y=var, data=res, and kind="count".
 - 2. Save the figure using f"res_{var}.png" as the filename.
- 14. Now we'll look into the nameplate capacity and cost of the systems in more detail. First, drop any records that are missing data for those specific fields. (FAQ2)
- 15. Then, set n_now to the new length of res and print an informative message indicating the number of records dropped.
- 16. Now create a figure with two panels in a row by setting fig, (ax1,ax2) to the result of calling plt.subplots(1,2). The 1 and 2 in the call indicate the number of rows and columns of panels in the plot.
- 17. Next, call .plot.hist() on the "nameplate" column of res with the argument ax=ax1 to put the histogram in the left panel. Just to be clear, this is a straight pandas call: we're not using seaborn yet.
- 18. Use the .set_title() method of ax1 to set its title to "Nameplate".
- 19. Now call <code>.plot.hist()</code> on the "total_cost" column of res with the argument <code>ax=ax2</code>. Then set its title to "Cost".
- 20. Tighten the figure's layout using .tight_layout() . (FAQ3)
- 21. If all has gone well you should end up with a pretty meaningless pair of histograms: there will be a single bar at the left in each one. That's because there are a few projects in the dataset with much larger capacities or costs than normal for residential projects. Now we'll remove the projects above the 99th percentile in size or cost. Start by setting kw99 equal to the result of calling .quantile(0.99) on the "nameplate" column of res. That will pick out the nameplate capacity at the 99th percentile. Then use a similar process to set tc99 to 99th percentile of the "total_cost" column of res.
- 22. Print an informative message giving kw99 and tc99.
- 23. Create a new dataframe called trim by calling the .query() method on res with the argument f"nameplate <= {kw99} and total_cost <= {tc99}".
- 24. Print the new number of records in trim to make sure a reasonable number (between 1 and 2 percent) were removed.

- 25. Now repeat the steps used to construct the two-panel figure above but using dataframe trim instead of res. If all goes well you should see two much nicer histograms.
- 26. Save the figure as "res_nameplate_cost.png".
- 27. Now we'll use seaborn to do some comparisons of projects with different values of the "third_party" variable. Use var to loop over a list consisting of the column names "nameplate" and "total_cost" Within the loop do the following:
 - 1. Create a new figure by setting fig, ax1 equal to the result of calling plt.subplots(). Please note: use the same statement for the rest of the semester whenever the instructions say to create a new single-panel figure and don't say explicitly how to do it. When doing so, include the dpi=300 argument if the script doesn't set the default resolution using plt.rcParams.
 - 2. Call sns.histplot() using the following arguments: data=trim, x=var, hue= "third_party", kde=True, and ax=ax1. The hue argument will cause superimposed histograms to be drawn for different values of "third_party", and the kde argument will cause a kernel density estimate of the distribution to be added to the plot.
 - 3. Tighten the figure's layout and then save it using the name f"res_{var}.png".
- 28. Another way to look at the distributions is to use boxen plots, which are a much-enhanced version of box plots. Create a new single-panel figure and then call sns.boxenplot() with the following arguments: data=trim, x="third_party", y="nameplate", and ax=ax1.
- 29. Then set the title for ax1 to "Nameplate Capacity", the label for the X axis to "Third Party", and the label for the Y axis to "kW". (FAQ4)
- 30. Tighten the figure's layout and then save it as "res_boxen_all.png".
- 31. Yet another approach is to use violin plots, which show kernel density estimates. Create a new single-panel figure and then call sns.violinplot() with the following arguments: data=trim, x="nameplate", y="inst_status", hue="third_party", split=True, and ax=ax1. Notice that the top and bottom distributions differ since the call requests a split violin plot. Also, if "inst_status" took on multiple values there would be a separate horizontal spine for each one.
- 32. Set the title to "Nameplate Capacity", the X label to "kW", the Y label to "" (an empty string), tighten the layout, and then save the figure as "res_violin.png".
- 33. Another option is to overlay the density estimates in a single figure. To do that, create a new single-panel figure and then call <code>sns.kdeplot()</code> with the following arguments: <code>data=trim</code>, <code>x="nameplate"</code>, <code>hue="third_party"</code>, <code>palette="crest"</code>, <code>fill=True</code>, and <code>ax=ax1</code>. The <code>palette</code> keyword picks out the color palette that will be used to distinguish between the curves, and <code>fill=True</code> says that the areas under the curves should be filled in. Then set the title to <code>"Nameplate Capacity"</code>, the X label to <code>"kW"</code>, tighten the layout, and save the figure as <code>"res_kde.png"</code>
- 34. Now we'll look in more detail at projects by year. First, trim off the last few years when the program was essentially over by setting main equal to the result of calling .query() on trim with the argument "year <= 2016".
- 35. Create a new single-panel figure and then call sns.boxenplot() with the following arguments: data=main, y="year", x="nameplate", orient="h", and ax=ax1. The orient keyword causes the boxes to be drawn horizontally. It's worth noting that swapping the X and Y variables will not change the orientation of a boxen plot: you must use the orient keyword.

- 36. Set the title for ax1 to "Nameplate Capacity by Year", the label for the X axis to "kW", and the label for the Y axis to "Year".
- 37. Tighten the figure's layout and then save it as "res_boxen_year.png".
- 38. Finally, we'll show the joint distribution of "nameplate" and "total_cost" using a hex plot. A hex plot is essentially an enhanced scatter plot for large datasets: it shows the density of points using colors that vary in intensity. The function we'll use produces a high-level seaborn JointGrid graphics object and does not require that plt.subplots() be called first. To create the plot, set jg equal to the result of calling sns.jointplot() with the following arguments: data=trim, x="nameplate", y="total_cost", and kind="hex".
- 39. Set the labels of the X and Y axes by calling the <code>.set_axis_labels()</code> method of <code>jg</code> with the arguments <code>"Nameplate"</code> and <code>"Total Cost"</code>. Note that this differs from the way labels are set on individual Axes objects.
- 40. Now set the overall title by calling jg.fig.suptitle() with the argument "Distribution of Systems by Cost and Ca As you can probably tell, jg.fig provides access to the Matplotlib Figure object embedded in seaborn's JointGrid object.
- 41. Then call jg.fig.tight_layout() to tidy up the layout.
- 42. Finally, use the .savefig() method of jg with argument "res_hexbin.png" to save the figure.

Submitting

Once you're happy with everything and have committed all of the changes to your local repository, please push the changes to GitHub. At that point, you're done: you have submitted your answer.

Notes

Constructing figures can be confusing because of several kinds of objects are involved. In Matplotlib itself, the workhorse objects are Axes and Figures. Seaborn adds additional complication because some of its functions return Axes, some return Figures, and some return higher-level objects (FacetGrid, JointGrid, and PairGrid objects). The Axes and Figure objects can be tweaked using standard Matplotlib calls but the three seaborn grid objects are more complex and have their own sets of methods.

FAQ

1. How do I change the datatype of a column?

Use the .astype() method on the column and store the result back in the dataframe under the original name. For example, to change the datatype of D["c"] to int, use D["c"] = D["c"].astype(int).

2. How do I drop records that are missing data in specific columns?

To drop records from dataframe D that are missing data for any of the columns in list L use D = D.dropna(subset=L)

3. How do I tighten the figure's layout?

To tighten the layout of figure F use F.tight_layout(). Keep in mind that this method applies to figures, not axes.

4. How do I add titles and labels to a Matplotlib axes object?

To set the title of axes object A to "words" use A.set_title("words"). To set the X label to "words" use A.set_xlabel("words"). Set the Y label in an analogous way.
